

2. Fat-Soluble Vitamins and Nutrients

Vitamins A and E and Carotenoids

- Vitamin A
- Retinyl palmitate
- Retinyl stearate
- Vitamin E
- *gamma*-Tocopherol
- *alpha*-Carotene
- *trans-beta*-Carotene
- *cis-beta*-Carotene
- *beta*-Cryptoxyanthin
- Lutein and zeaxanthin
- *trans*-Lycopene
- Total lycopene (*cis*- and *trans*-)

Vitamin D

- 25-Hydroxyvitamin D

Fatty Acids

Saturated

- Myristic acid (14:0)
- Palmitic acid (16:0)
- Stearic acid (18:0)
- Arachidic acid (20:0)
- Docosanoic acid (22:0)
- Lignoceric acid (24:0)

Monounsaturated

- Myristoleic acid (14:1n-5)
- Palmitoleic acid (16:1n-7)
- *cis*-Vaccenic acid (18:1n-7)
- Oleic acid (18:1n-9)
- Eicosenoic acid (20:1n-9)
- Docosenoic acid (22:1n-9)
- Nervonic acid (24:1n-9)

Polyunsaturated

- Linoleic acid (18:2n-6)
- *alpha*-Linolenic acid (18:3n-3)
- *gamma*-Linolenic acid (18:3n-6)
- Eicosadienoic acid (20:2n-6)
- *homo-gamma*-Linolenic acid (20:3n-6)
- Arachidonic acid (20:4n-6)
- Eicosapentaenoic acid (20:5n-3)
- Docosatetraenoic acid (22:4n-6)
- Docosapentaenoic acid (22:5n-3)
- Docosapentaenoic acid (22:5n-6)
- Docosahexaenoic acid (22:6n-3)

Vitamins A, E and Carotenoids

Background Information

Sources and Physiological Functions. Vitamins A (retinol) and E (*alpha*-tocopherol) and the carotenoids are fat-soluble micronutrients found in many foods, including some vegetables, fruits, meats, and animal products. Fish-liver oils, liver, egg yolks, butter, and cream are known for their higher content of vitamin A. Nuts and seeds are particularly rich sources of vitamin E (Thomas 2006). At least 700 carotenoids—fat-soluble red and yellow pigments—are found in nature (Britton 2004). Americans consume 40–50 of these carotenoids, primarily in fruits and vegetables (Khachik 1992), and smaller amounts in poultry products, including egg yolks, as well as in seafoods (Boylston 2007). Eight different carotenoids are easily measured in human serum: *alpha*-carotene, *cis*- and *trans*-*beta*-carotene, *beta*-cryptoxanthin, lutein, *cis*- and *trans*-lycopene, and zeaxanthin. Main sources of carotenes are orange-colored fruits and vegetables such as carrots, pumpkins, and mangos. Lutein and zeaxanthin are also found in dark green leafy vegetables, where any orange coloring is overshadowed by chlorophyll. *Trans*-lycopene is obtained primarily from tomatoes and tomato products and some fruits. For information on the carotenoid content of U.S. foods, see the 1998 carotenoid database created by the U.S. Department of Agriculture and the Nutrition Coordinating Center at the University of Minnesota (<http://www.nal.usda.gov/fnic/foodcomp/Data/car98/car98.html>).

Vitamin A, found in foods that come from animal sources, is called preformed vitamin A. Some carotenoids found in colorful fruits and vegetables are called provitamin A because they are metabolized in the body to vitamin A. Among the carotenoids, *beta*-carotene, a retinol dimer consisting of two linked retinol molecules, has the most significant provitamin A activity. Approximately 12 micrograms (μg) of dietary *beta*-carotene can provide the equivalent of 1 μg of retinol. Other provitamin A carotenoids, such as *alpha*-carotene and *beta*-cryptoxanthin, are half as active as *beta*-carotene (Institute of Medicine 2000). The bioconversion of carotenoids to vitamin A is highly variable from person to person (Krinsky 2005). Retinyl esters serve as the storage form of vitamin A and are mostly concentrated in the liver.

The absorption of fat-soluble micronutrients from the gastrointestinal tract depends on processes responsible for fat absorption or metabolism. Thus, people with conditions resulting in fat malabsorption (e.g., celiac disease, Crohn's disease, pancreatic disorders) can develop vitamin A deficiency over time. Vitamin A also has interactions with other nutrients. Iron and zinc deficiency can affect vitamin A metabolism and transport of vitamin A stores from the liver to body tissues (Institute of Medicine 2001). The absorption of carotenoids from foods is highly dependent on cooking techniques that break down plant cell walls and release carotenoids; it is also dependent on the availability of dietary fat to enhance carotenoid uptake (Krinsky 2005). The liver regulates the concentration of vitamin A in the circulation by releasing stored retinyl esters as needed; only when liver reserves are nearly exhausted does serum vitamin A fall into the deficient range (Napoli 2006). The variation in serum carotenoid concentrations among people in the United States is relatively large, primarily reflecting wide-ranging differences in dietary intake (Lacher 2005).

Vitamin E activity is derived from at least eight naturally occurring tocopherols, the most potent of which is *alpha*-tocopherol. Other less active forms of vitamin E are plentiful in the U.S. diet, with *gamma*-tocopherol being the predominant form. The most commonly consumed sources of *alpha*-tocopherol in the diet of American adults are mixed foods (spaghetti sauce, pizza and chili), fried potatoes, salad dressings, and bakery goods (Ahuja 2004). Other important sources are

tomatoes, eggs, nuts and seeds, and snack foods. Plasma concentrations of tocopherols vary widely among healthy individuals and are highly correlated with plasma lipid concentrations (Ford 1999; Ford 2006).

Health Effects. Inadequate or excessive intake of vitamins A or E can lead to various disorders. For example, vitamin A deficiency, considered to be the main cause of childhood blindness in low-income countries (Roodhooft 2002), is a rare condition in the United States. Prominent signs of vitamin A deficiency include night blindness, corneal thinning, and conjunctival metaplasia. Vitamin A is also essential for proper immune function, epithelial growth and repair, bone growth, reproduction, and normal embryonic and fetal development (West 2006). Acute toxicity resulting from single or short-term large doses of preformed vitamin A is characterized by nausea, vomiting, headache, vertigo, blurred vision, increased cerebrospinal fluid pressure, and lack of muscular coordination. Central nervous system effects, liver abnormalities, bone and skin changes, and other nonspecific adverse effects can be indicative of chronic hypervitaminosis A. Consuming excess amounts of vitamin A during early pregnancy may lead to serious birth defects (Institute of Medicine 2001).

Serum or plasma concentrations of carotenoids are considered among the best biological markers for fruit and vegetable intake. The strongest dietary predictors of serum carotenoid concentrations are fruits (for sources of *beta*-cryptoxanthin), carrots and root vegetables (for sources of carotenes), and tomato products (for sources of *trans*-lycopene) (Al-Delaimy 2005). Research studies have shown inconsistencies in the relation between carotenoid intake and protection from cancer. Carotenoids in foods, even when consumed over long periods and in large amounts are not known to produce adverse health effects. However, results of intervention studies of smokers who used 20–30 milligrams (mg) of *beta*-carotene per day showed that this group had more lung cancers than placebo-treated groups (Albanes 1996; Redlich 1998).

Vitamin E deficiency occurs only rarely in people, and overt deficiency symptoms in people consuming low-vitamin E diets have never been described (Institute of Medicine 2000). The main manifestation of vitamin E deficiency is peripheral neuropathy characterized by the degeneration of the large-caliber axons of sensory neurons (Institute of Medicine 2000). The upper limit (UL) for vitamin E intake (1000 mg/day) is based on hemorrhagic effects; however, a causal association between excess *alpha*-tocopherol intake in apparently healthy individuals and adverse health outcomes has not consistently been shown (Institute of Medicine 2000). Studies evaluating tocopherols to reduce the risk for cardiovascular disease demonstrated inconsistent findings (Agency for Healthcare Research and Quality 2003). The American Heart Association currently advises that antioxidant supplements (such as vitamins E and C and *beta*-carotene) should not be used for primary or secondary prevention of cardiovascular disease (Lichtenstein 2006). Nevertheless, the American Heart Association recommends consuming food sources of antioxidant nutrients, principally from a variety of plant-derived foods such as fruits, vegetables, whole grains, and vegetable oils.

Intake Recommendations. The National Academy of Sciences has established dietary-requirement intake values for vitamins A and E by determining the Adequate Intake (AI) for infants and the recommended dietary allowance (RDA) for older age groups (Institute of Medicine 2000 and 2001). The RDA for vitamin A in retinol equivalents is 900 µg/day for men and 700 µg/day for women; for children and adolescents (1–18 years), the RDA ranges from 300–900 µg/day. For infants (0–12 months), the AI is set at 400–500 µg/day of retinol equivalents. The Tolerable Upper Intake Level (UL) for adults is set at 3,000 µg/day of preformed vitamin A, whereas the UL for infants (600 µg/day), younger children 1–8 years (600–900 µg/day), older children 9–13 years (1700 µg/day), and

adolescents 14–18 years (2800 µg/day) are age-dependent. For adults, the RDA for vitamin E is 15 mg/day of *alpha*-tocopherol; for children and adolescents (1–18 years), the RDA ranges from 6–15 mg/day. There is no RDA for other forms of vitamin E, such as *gamma*-tocopherol. The UL for vitamin E which applies to all eight stereoisomers of *alpha*-tocopherol is 1000 mg/day for adults; a UL for infants could not be established and thus only food and formula sources of dietary intake are recommended. The UL for children and adolescents ranges from 200–800 mg/day of vitamin E. Although no quantitative recommendations are available for the intake of carotenoids, existing recommendations support increased consumption of carotenoid-rich fruits and vegetables. Current public health guidelines advise that people consume at least 2.5 cups of fruits and vegetables a day, depending on caloric need, to ensure adequate nutrient intake (U.S. Department of Agriculture and U.S. Department of Health and Human Services 2010).

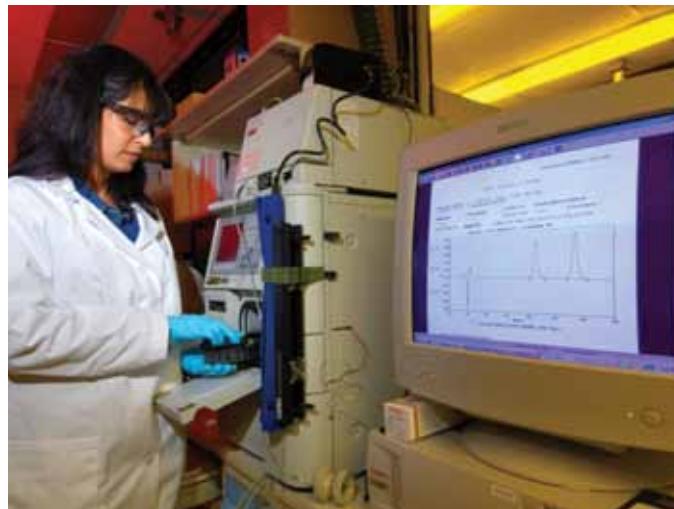

Biochemical Indicators and Methods. The best way to determine inadequate vitamin A status is through hepatic biopsy, but this invasive procedure is unsuitable for population studies. Serum or plasma retinol is measured by use of high performance liquid chromatography (HPLC) with ultraviolet (UV) detection after separation from its carrier retinol binding protein (RBP). Because retinol is closely correlated with RBP, the measurement of this transport protein through enzyme-linked immunosorbent assay (ELISA) has also been used to assess vitamin A status. In most populations, serum RBP has been shown to be a suitable surrogate for retinol. Serum or plasma concentrations of carotenoids are measured by use of HPLC and visible light (450 nm) absorbance.

Clinical laboratories typically use conventional units for serum concentrations of these fat-soluble micronutrients (µg per deciliter [dL]). Conversion factors to international system (SI) units are 1 µg/dL = 0.0349 micromole per liter (µmol/L) for vitamin A and 1 µg/dL = 0.02322 µmol/L for vitamin E. Depending on its molecular weight, each carotenoid has a specific conversion factor.

International reference materials for vitamins A and E and carotenoids are available from the U.S. National Institutes of Standards and Technology (https://www-s.nist.gov/srmors/view_detail.cfm?srn=968e). Among most laboratories participating in an external quality assurance program, standardized HPLC methods for measuring fat-soluble micronutrients show consistent agreement of values (Duewer 2000).

The diagnosis of vitamin A or E deficiency is supported by measuring these concentrations in the body. People with serum retinol concentrations of less than 20 µg/dL are considered vitamin A deficient, and those with serum concentrations of less than 10 µg/dL are considered severely deficient (West 2006). Serum retinol values do not always reflect total body status because of homeostatic

control and therefore are often not useful for assessing the vitamin A status of individuals. Additional tests may be required to confirm vitamin A deficiency when 20 µg/dL is used as a cutoff (Gibson 2005). The distribution of serum retinol values in a population together with the prevalence of individuals with serum retinol values below a given cutoff point provide important information about the vitamin A status of a population. WHO (2011) recommends using the prevalence of serum retinol concentrations of less than or equal to 20 µg/dL to define public health problems involving vitamin A deficiency as mild (2–9%), moderate (10–19%) or severe (≥20%). In chronic hypervitaminosis A, serum concentrations are generally greater than 100 µg/dL (Bendich 1989). Carotenoid

deficiency has no defined serum concentrations. The laboratory diagnosis of vitamin E deficiency is based on serum concentrations of alpha-tocopherol (less than 500 µg/dL or less than 0.8 mg of alpha-tocopherol per gram of total lipids) (Beers 2006). Such concentrations are associated with in vitro hydrogen peroxide-induced red blood cell lysis, not with clinical deficiency symptoms (Institute of Medicine 2000).

Data in NHANES. The fat-soluble micronutrients vitamin A, E, and carotenoids presented in this report were measured by a single assay panel employing HPLC separation and detection by use of UV or visible light (HPLC-UV/vis). This is the same method used during the first four years of the continuous NHANES survey (1999–2002).

Since 1971, various fat-soluble micronutrients have been measured in the serum of NHANES participants. In NHANES III (1988–1994), clinically low concentrations of serum retinol were uncommon in U.S. residents aged 4 years and older, although racial/ethnic and socioeconomic differences existed (Ballew 2001). Variations in serum carotenoid concentrations by ethnicity and sex were found for adults, children, and adolescents (Ford 2000; Ford 2002). Ford *et al.* also found sociodemographic variations in serum concentrations of *alpha*-tocopherol among U.S. adults in NHANES III (1999) and *alpha*- and *gamma*-tocopherol in NHANES 1999–2000 (2006). Application of the most common cut-off value for serum *alpha*-tocopherol concentrations in NHANES 1999–2000 (500 µg/dL), demonstrated a low prevalence of vitamin E deficiency, despite the fact that the U.S. Department of Agriculture-estimated dietary intakes of vitamin E were low and that most of the U.S. population did not meet dietary intake recommendations.

For more information on these fat-soluble micronutrients, see the Institute of Medicine's Dietary Reference Intake reports (Institute of Medicine 2000 and 2001) and the vitamin fact sheets from the National Institutes of Health, Office of Dietary Supplements (http://ods.od.nih.gov/Health_Information/Vitamin_and_Mineral_Supplement_Fact_Sheets.aspx).

Highlights

Serum concentrations of fat-soluble micronutrients (vitamin A, E, and carotenoids) in the U.S. population showed the following demographic patterns and characteristics:

- With few exceptions, the highest concentrations of fat-soluble micronutrients were found in persons 60 years and older.
- No consistent pattern was observed with regard to gender or race/ethnicity.
- The likelihood of being vitamin A or E deficient was very low throughout the population.
- The likelihood of vitamin A excess was also very low, but it increased with increasing age.

For more than 20 years, the majority of the U.S. population (greater than 95%) has had adequate serum concentrations of vitamin A ($\geq 20 \mu\text{g}/\text{dL}$) and vitamin E ($\geq 500 \mu\text{g}/\text{dL}$).

Despite NHANES 2001–2002 dietary intake data demonstrating that 93% of the U.S. population consumed less than the Estimated Average Requirement (EAR) for vitamin E (Moshfegh 2005), for decades mean serum vitamin E concentrations have remained consistently adequate (Figure H.2.a), with less than 1% of the population vitamin E deficient. Analyses of NHANES data showed that in 1999–2000, 52% of adults (Rock 2007) and in 2003–2006, 49% of the total U.S. population (Bailey 2011) used dietary supplements; thus, the intake data (food and supplements) for vitamin E seem to be inconsistent with the biomarker data. Several explanatory possibilities have been raised, including a suggestion that the intake of fats (and

fat-soluble nutrients) is under-reported in overweight and obese subjects, the database of food values is not accurate, and/or that the EAR for vitamin E needs adjustment. Low intake without widespread manifestation of deficiency suggests the need for further evaluations to determine whether improved estimates are necessary, either in the nutrient tables or in dietary intake.

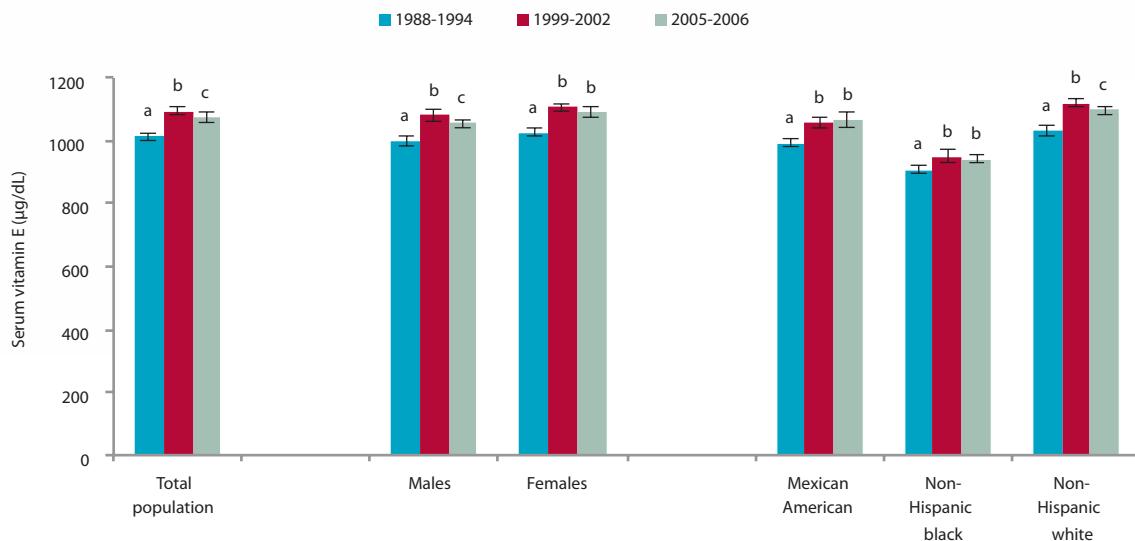

Figure H.2.a. Age-adjusted geometric mean concentrations of serum vitamin E (alpha-tocopherol) in the U.S. population aged 6 years and older by gender or race/ethnicity, National Health and Nutrition Examination Survey, 1988–2006.

Error bars represent 95% confidence intervals. Within a demographic group, bars not sharing a common letter differ ($p < 0.05$). Age adjustment was done using direct standardization.

Detailed Observations

The selected observations mentioned below are derived from the tables and figures presented next. Statements about categorical differences between demographic groups noted below are based on non-overlapping confidence limits from univariate analysis without adjusting for demographic variables (e.g., age, gender, race/ethnicity) or other blood concentration determinants (e.g., dietary intake, supplement usage, smoking, BMI). A multivariate analysis may alter the size and statistical significance of these categorical differences. Furthermore, additional significant differences of smaller magnitude may be present despite their lack of mention here (e.g., if confidence limits slightly overlap or if differences are not statistically significant before covariate adjustment has occurred). For a selection of citations of descriptive NHANES papers related to these biochemical indicators of diet and nutrition, see [Appendix G](#).

Geometric mean concentrations (NHANES 2005–2006):

- Serum vitamin A concentrations increased with age (Table 2.1.a.1 and Figure 2.1.a).
- Serum retinyl palmitate concentrations were similar across age ranges, with a slight decrease in the adolescent years (Table 2.2.a.1 and Figure 2.2.a).
- Serum vitamin E concentrations decreased throughout childhood, then increased with age to concentrations higher than those seen in early childhood (Table 2.4.a.1 and Figure 2.4.a), while serum *gamma*-tocopherol concentrations remained relatively constant throughout the life cycle, decreasing slightly in older persons (Table 2.5.a.1 and Figure 2.5.a).

- Serum *alpha*-carotene, *trans-beta*-carotene, and lutein/zeaxanthin concentrations decreased throughout childhood, then increased with age to concentrations higher than those seen in early childhood (Tables 2.6.a.1, 2.7.a.1, and 2.10.a.1 and Figures 2.6.a, 2.7.a, 2.10.a).
- Serum *beta*-cryptoxanthin concentrations decreased in early childhood and then remained steady (Table 2.9.a.1 and Figure 2.9.a).
- Serum *trans*-lycopene and total lycopene concentrations were highest in young adults and lowest in older persons (Tables 2.11.a.1 and 2.12.a.1 and Figures 2.11.a, 2.12.a).
- Females had higher serum vitamin E than males, while males had higher serum vitamin A concentrations than females (Tables 2.4.a.1 and 2.1.a.1).
- Females had higher serum *alpha*-carotene and *trans-beta*-carotene concentrations than males, and males had higher serum total lycopene concentrations than females (Tables 2.6.a.1, 2.7.a.1, and 2.12.a.1).
- Non-Hispanic whites had the highest concentrations of serum vitamin A and vitamin E, and the lowest concentrations of serum *gamma*-tocopherol. Non-Hispanic whites had the lowest concentrations of serum lutein/zeaxanthin. Non-Hispanic blacks had the lowest concentrations of serum *alpha*-carotene. Mexican Americans had the highest concentrations of serum *beta*-cryptoxanthin and the lowest concentrations of serum *trans*-lycopene and total lycopene. (Tables 2.1.a.1, 2.4.a.1, 2.5.a.1, 2.10.a.1, 2.6.a.1, 2.9.a.1, 2.11.a.1, and 2.12.a.1).

Changes in geometric mean concentrations across survey cycles:

- Serum vitamin A concentrations increased between 1999–2000 and 2001–2002, then held steady through the 2005–2006 survey period (Table 2.1.b).
- Serum vitamin E and *gamma*-tocopherol concentrations held steady between 1999–2000 and 2005–2006 (Tables 2.4.b and 2.5.b).
- Serum *alpha*-carotene, *trans-beta*-carotene, *beta*-cryptoxanthin, lutein/zeaxanthin, and *trans*-lycopene concentrations did not change appreciably across the survey cycles (Tables 2.6.b, 2.7.b, 2.9.b, 2.10.b, and 2.11.b).
- Prevalence estimates of low or high biochemical indicator concentrations:
- In 2005–2006, less than 1% of the population aged 6 years and older had a vitamin A or vitamin E deficiency, defined as < 20 µg/dL and < 500 µg/dL, respectively (Tables 2.1.c.1 and 2.4.c). About 2%, however, were at risk for an excess of vitamin A, or > 100 µg/dL (Table 2.1.c.2).
- Between 1999 and 2006, the prevalence of low serum vitamin A was less than 1% of all persons (Table 2.1.d.1), and the prevalence of high serum vitamin A was 1–2% of all persons (Table 2.1.d.2).
- Between 1999 and 2006, the prevalence of low serum vitamin E was 2% or less for almost all groups except for adolescents, for whom the prevalence was 2–4% (Table 2.4.d).

Table 2.1.a.1. Serum vitamin A: Concentrations

Geometric mean and selected percentiles of serum concentrations (in µg/dL) for the total U.S. population aged 6 years and older,
National Health and Nutrition Examination Survey, 2005–2006.

Geometric mean (95% conf. interval)	Selected percentiles (95% conf. interval)				Sample size
	2.5th	5th	50th	95th	
Total, 6 years and older	54.7 (53.8 – 55.6)	29.6 (28.7 – 30.5)	32.5 (31.8 – 33.2)	55.2 (54.2 – 56.1)	87.8 (85.6 – 90.5)
Age group					96.7 (93.1 – 101)
6–11 years	36.4 (35.6 – 37.2)	22.8 (19.9 – 24.8)	25.6 (24.3 – 26.9)	36.6 (35.9 – 37.3)	52.4 (49.1 – 54.3)
12–19 years	46.5 (45.4 – 47.7)	28.9 (28.6 – 29.6)	32.0 (30.6 – 33.0)	46.0 (44.6 – 47.5)	69.6 (66.9 – 73.1)
20–39 years	54.3 (53.3 – 55.3)	31.2 (29.2 – 32.1)	33.9 (32.2 – 35.1)	54.7 (53.5 – 55.6)	84.4 (81.9 – 87.9)
40–59 years	58.7 (57.7 – 59.7)	33.1 (31.4 – 34.2)	36.8 (36.0 – 38.0)	59.5 (58.1 – 60.4)	90.3 (87.2 – 94.3)
60 years and older	64.4 (62.8 – 66.1)	36.4 (31.6 – 38.8)	40.2 (38.2 – 43.0)	64.9 (63.1 – 67.0)	99.8 (96.2 – 102)

< LOD means less than the limit of detection, which may vary for some compounds by year. See Appendix D for LOD.

Figure 2.2.b. Serum retinyl palmitate: Concentrations by survey cycle

Selected percentiles in µg/dL (95% confidence intervals), National Health and Nutrition Examination Survey, 1999–2002 and 2005–2006

Values in the graph are suppressed if either the point estimate or the lower 95% confidence limit is noted as “< LOD” in the accompanying table.

Table 2.3.a.1. Serum retinyl stearate: Concentrations

Geometric mean and selected percentiles of serum concentrations (in µg/dL) for the total U.S. population aged 6 years and older, National Health and Nutrition Examination Survey, 2005–2006.

Geometric mean (95% conf. interval)	Selected percentiles (95% conf. interval)				Sample size
	2.5th	5th	50th	95th	
Total, 6 years and older	< LOD	< LOD	< LOD	1.31 (1.23 – 1.48)	1.95 (1.79 – 2.09)
Age group					6,698
6–11 years	*	< LOD	< LOD	1.33 (1.08 – 1.97)	1.97 (1.65 – 4.08)
12–19 years	*	< LOD	< LOD	.911 (.743 – 1.14)	1.48 (1.18 – 2.00)
20–39 years	*	< LOD	< LOD	.947 (.850 – 1.09)	1.32 (1.14 – 1.76)
40–59 years	*	< LOD	< LOD	1.35 (1.23 – 1.63)	2.00 (1.68 – 2.31)
60 years and older	*	< LOD	< LOD	1.93 (1.59 – 2.58)	2.77 (2.26 – 3.58)
Gender					
Males	*	< LOD	< LOD	1.40 (1.29 – 1.54)	1.94 (1.86 – 2.05)
Females	*	< LOD	< LOD	1.25 (1.09 – 1.48)	1.99 (1.62 – 2.34)
Race/ethnicity					
Mexican Americans	*	< LOD	< LOD	.933 (.792 – 1.19)	1.35 (1.08 – 2.07)
Non-Hispanic Blacks	*	< LOD	< LOD	.896 (.829 – 1.10)	1.38 (1.10 – 1.71)
Non-Hispanic Whites	*	< LOD	< LOD	1.50 (1.36 – 1.64)	2.06 (1.93 – 2.36)

< LOD means less than the limit of detection, which may vary for some compounds by year. See Appendix D for LOD.

* Not calculated. Proportion of results below limit of detection was too high to provide a valid result.

No serum retinyl stearate figure for concentrations by age group is presented because the geometric means were not calculated due to the proportion of results below the limit of detection being too high for valid results (see Table 2.3.a.1).

Table 2.3.a.2. Serum retinyl stearate: Total population

Geometric mean and selected percentiles of serum concentrations (in µg/dL) for the total U.S. population aged 6 years and older, National Health and Nutrition Examination Survey, 2005–2006.

	Geometric mean (95% conf. interval)	Selected percentiles (95% conf. interval)			Sample size
		10th	50th	90th	
Males and Females					
Total, 6 years and older	*	< LOD	< LOD	.894 (.794 – 1.02)	6,698
6–11 years	*	< LOD	< LOD	.972 (.730 – 1.21)	792
12–19 years	*	< LOD	< LOD	< LOD	1,801
20–39 years	*	< LOD	< LOD	< LOD	1,555
40–59 years	*	< LOD	< LOD	.944 (.810 – 1.16)	1,262
60 years and older	*	< LOD	< LOD	1.32 (1.13 – 1.58)	1,288
Males					
Total, 6 years and older	*	< LOD	< LOD	.964 (.871 – 1.08)	3,276

Non-Hispanic Whites	*	< LOD	< LOD	< LOD	1,673
					2,725

< LOD means less than the limit of detection, which may vary for some compounds by year. See Appendix D for LOD.

* Not calculated. Proportion of results below limit of detection was too high to provide a valid result.

No *cis-beta*-carotene figure for concentrations by age group is presented because the geometric means were not calculated due to the proportion of results below the limit of detection being too high for valid results (see Table 2.8.a.1).

Table 2.8.a.2. Serum cis-beta-carotene: Total population

Geometric mean and selected percentiles of serum concentrations (in µg/dL) for the total U.S. population aged 6 years and older, National Health and Nutrition Examination Survey, 2005–2006.

	Geometric mean (95% conf. interval)	Selected percentiles (95% conf. interval)			Sample size

< LOD means less than the limit of detection, which may vary for some compounds by year. See Appendix D for LOD.

* Not calculated. Proportion of results below limit of detection was too high to provide a valid result.

† Estimate is subject to greater uncertainty due to small cell size.

Table 2.8.a.4. Serum cis-beta-carotene: Non-Hispanic blacks

Geometric mean and selected percentiles of serum concentrations (in µg/dL) for non-Hispanic blacks in the U.S. population aged 6 years and older, National Health and Nutrition Examination Survey, 2005–2006.

	Geometric mean (95% conf. interval)	Selected percentiles (95% conf. interval)			Sample size
		10th	50th	90th	
Males and Females					
Total, 6 years and older	*	< LOD	< LOD	1.87 (1.59 – 2.49)	1,673
6–11 years	*	< LOD	< LOD	1.33 (1.12 – 2.11)	208
12–19 years	*	< LOD	< LOD	1.05 (.916 – 1.20)	580
20–39 years	*	< LOD	< LOD	1.41 (1.24 – 1.84)	327
40–59 years	*	< LOD	.778 (< LOD – .937)	2.54 (2.16 – 3.11)	298
60 years and older	1.04 (.906 – 1.19)	< LOD	.965 (.778 – 1.09)	2.80 (2.23 – 3.45)	260
Males					
Total, 6 years and older	*	< LOD	< LOD	1.61 (1.33 – 1.94)	827
6–11 years	.807 (.695 – .937)	< LOD	.738 (< LOD – .876)	1.45 (1.13 – 6.80)	112
12–19 years	*	< LOD	< LOD	.997 (.882 – 1.17)	290
20–39 years	*	< LOD	< LOD	1.27 (.962 – 1.84)	149
40–59 years	*	< LOD	< LOD	2.28 (1.51 – 3.29)	136
60 years and older	*	< LOD	.784 (< LOD – .927)	1.95 (1.64 – 3.14)	140
Females					
Total, 6 years and older	*	< LOD	.717 (< LOD – .832)	2.20 (1.83 – 2.77)	846
6–11 years	*	< LOD†	< LOD	1.19† (1.03 – 1.99)	96
12–19 years	*	< LOD	< LOD	1.08 (.914 – 1.42)	290
20–39 years	*	< LOD	< LOD	1.62 (1.25 – 2.76)	178
40–59 years	1.01 (.886 – 1.16)	< LOD	.877 (.765 – 1.03)	2.82 (2.25 – 3.43)	162
60 years and older	1.17 (.947 – 1.44)	< LOD	1.10 (.720 – 1.58)	3.16 (2.59 – 3.84)	120

< LOD means less than the limit of detection, which may vary for some compounds by year. See Appendix D for LOD.

* Not calculated. Proportion of results below limit of detection was too high to provide a valid result.

† Estimate is subject to greater uncertainty due to small cell size.

Table 2.8.a.5. Serum cis-beta-carotene: Non-Hispanic whites

Geometric mean and selected percentiles of serum concentrations (in µg/dL) for non-Hispanic whites in the U.S. population aged 6 years and older, National Health and Nutrition Examination Survey, 2005–2006.

	Geometric mean (95% conf. interval)	Selected percentiles (95% conf. interval)			Sample size
		10th	50th	90th	
Males and Females					
Total, 6 years and older	*	< LOD	< LOD	2.17 (1.92 – 2.55)	2,725
6–11 years	*	< LOD	< LOD	1.46 (1.21 – 2.42)	212
12–19 years	*	< LOD	< LOD	1.16 (.979 – 1.39)	462
20–39 years	*	< LOD	< LOD	1.74 (1.44 – 2.15)	653
40–59 years	*	< LOD	.720 (< LOD – .779)	2.50 (2.11 – 3.14)	634
60 years and older	1.07 (.967 – 1.18)	< LOD	.892 (.783 – 1.00)	3.09 (2.57 – 3.70)	764

Vitamin D

Background Information

Sources and Physiological Functions. Vitamin D (calciferol) comprises a group of fat soluble seco-sterols found naturally in only a few foods, such as fish-liver oils, fatty fishes, mushrooms, egg yolks, and liver. The two major physiologically relevant forms of vitamin D are D₂ (ergocalciferol) and D₃ (cholecalciferol). Vitamin D₃ is photosynthesized in the skin of vertebrates by the action of solar ultraviolet (UV) B radiation on 7-dehydrocholesterol present in the skin (Fieser 1959). Vitamin D₂ is produced by UV irradiation of ergosterol, which occurs in molds, yeast, and higher-order plants. Under conditions of regular sun exposure, dietary vitamin D intake is of minor importance. However, latitude, season, aging, sunscreen use, and skin pigmentation influence the production of vitamin D₃ by the skin (Institute of Medicine 2011). In the United States, most of the dietary intake of vitamin D comes from fortified milk products and other fortified foods such as breakfast cereals and orange juice (Institute of Medicine 2011). Both vitamin D₂ and D₃ are used in nonprescription vitamin D supplements, but vitamin D₂ is the only form available by prescription in the United States (Holick 2007).

Vitamin D without a subscript represents either D₂ or D₃ or both. Vitamin D, *per se*, is biologically inert. Whether derived from the skin or diet, vitamin D is only short-lived in circulation (with a half-life of 1–2 days), as it is either stored in fat cells or metabolized in the liver (Mawer 1972). In circulation, vitamin D is bound to vitamin D-binding protein and transported to the liver, where it is converted to 25-hydroxyvitamin D [25(OH)D] (DeLuca 1984). This major circulating form of vitamin D is a good reflection of cumulative effects of exposure to sunlight and dietary intake of vitamin D (Haddad 1973; Holick 1995) and is therefore used by clinicians to determine vitamin D status. To be biologically activated at physiologic concentrations, 25(OH)D must be converted in the kidneys to 1,25-dihydroxyvitamin D [1,25(OH)₂D], which is thought to be responsible for most, if not all, of the biologic functions of vitamin D (DeLuca 1988; Reichel 1989). The production of 25(OH)D in the liver is a function of vitamin D availability from dietary intake and sun exposure whereas production of 1,25(OH)₂D in the kidney is tightly regulated by mineral requirements. In the liver, vitamin D-25-hydroxylase is down-regulated by vitamin D and its metabolites, thereby limiting any increase in the circulating concentration of 25(OH)D following intakes or following production of vitamin D after exposure to sunlight. In the kidney, in response to serum calcium and phosphorus concentrations, the production of 1,25(OH)₂D is regulated through the action of parathyroid hormone (PTH) (DeLuca 1988; Reichel 1989).

Health Effects. Active vitamin D (1,25-dihydroxyvitamin D) functions as a hormone, and its main biologic function in people is to maintain serum calcium and phosphorus concentrations within the normal range by enhancing the efficiency of the small intestine to absorb these minerals from the diet (DeLuca 1988; Reichel 1989). When dietary calcium intake is inadequate to satisfy the body's calcium requirement, 1,25(OH)₂D, along with PTH, mobilizes calcium stores from the bone. In the kidney, 1,25(OH)₂D increases calcium reabsorption by the distal renal tubules. Apart from these traditional calcium-related actions, 1,25(OH)₂D and its synthetic analogs are increasingly recognized for their potent anti-proliferative, pro-differentiative, and immunomodulatory activities (Nagpal 2005).

Vitamin D deficiency is characterized by inadequate mineralization or by demineralization of the skeleton. Among children, vitamin D deficiency is a common cause of bone deformities known as rickets. Vitamin D deficiency in adults leads to a mineralization defect in the skeleton,

causing osteomalacia, and it induces secondary hyperparathyroidism with consequent bone loss and osteoporosis. Potential roles for vitamin D beyond bone health, such as effects on muscle strength, the risk for cancer, and the risk for type 2 diabetes, are under intense investigation. The Agency for Healthcare Research and Quality (AHRQ) reviewed the effectiveness and safety of vitamin D on outcomes related to bone health (Cranney 2007). The report suggests that vitamin D supplementation has positive effects on bone health in postmenopausal women and older men. Another AHRQ systematic review of vitamin D status and health outcomes found no significant associations between vitamin D status and total cancer mortality, nor did it find any conclusive evidence for the association of vitamin D status with cancer risk or cancer outcome (Chung 2009). It also found no clear association between vitamin D status and cardiometabolic outcomes including fasting glucose, blood pressure, myocardial infarction or stroke. Randomized trials showed no clinically significant consistent effects of vitamin D supplementation at the dosages given (Pittas 2010).

Intake Recommendations. What constitutes the optimal intake of vitamin D remains a matter of some disagreement. Current recommendations from the Institute of Medicine (2011) call for 400 international units (IU) [10 micrograms (μ g)] of vitamin D daily from birth through age 1 year for adequate intake (AI). The Recommended Dietary Allowance (RDA) for those aged 1–70 years is 600 IU (15 μ g) and 800 IU (20 μ g) for those older than 70 years. According to the Dietary Guidelines for Americans (U.S. Department of Agriculture and U.S. Department of Health Human Services 2010), moderate evidence shows that intake of milk and milk products is linked to improved bone health, especially in children and adolescents. In the United States, most dietary vitamin D is obtained from fortified foods, especially milk. The Tolerable Upper Intake Level for vitamin D is 4000 IU (100 μ g) per day in North America for individuals 9 years of age and older and ranges from 1000 IU to 3000 IU for infants and children less than 9 years of age; as intake increases above this amount, the potential risk for adverse consequences increases.

Biochemical Indicators and Methods. To assess vitamin D status, one measures the concentration of 25(OH)D in serum, using either antibody-based methods such as radioisotope-, enzyme-linked- or chemiluminescence- immunoassays, or using chemistry-based methods such as HPLC separation with UV or tandem mass spectrometry detection. Studies have shown that standardized chemistry-based methods are equivalent but that antibody-based methods may show significant bias. Some clinical laboratories use conventional units for 25(OH)D (nanogram per milliliter [ng/mL]), whereas other laboratories use international system (SI) units (nanomole per liter [nmol/L]). The conversion factor to SI units is: $1 \text{ ng/mL} = 2.5 \text{ nmol/L}$.

The Institute of Medicine (2011) committee to review dietary reference intakes for vitamin D and calcium suggested that persons with serum 25(OH)D concentrations of less than 30 nmol/L (12 ng/mL) are at risk for deficiency; those with concentrations of at least 30 but less than 50 nmol/L (12 to less than 20 ng/mL) are at risk for inadequacy; and those with concentrations between 50–75 nmol/L (20–30 ng/mL) are considered sufficient. The Committee indicated that concentrations greater than 125 nmol/L (50 ng/mL) may be reason for concern. Of interest

to public health scientists, the report indicated that a serum 25(OH)D level consistent with the Estimated Average Requirement for dietary intake (EAR) lies between 30 and 50 nmol/L and that 40 nmol/L was selected from the middle of the range to serve as the targeted level for median dietary requirements ([Institute of Medicine 2011](#)).

A number of external quality assurance programs exist for serum or plasma 25(OH)D concentration measurements, including those sponsored by DEQAS (Vitamin D External Quality Assessment Scheme), College of American Pathologists (Bone and Growth Survey and Accuracy-Based Vitamin D Survey), and NIST/NIH (Vitamin D Metabolites Quality Assurance Program). Standard reference materials (SRM 972) with certified values for 25(OH)D₂, 25(OH)D₃ and C3-epimer of 25(OH)D₃ are available from the U.S. National Institute of Standards and Technology (NIST). An additional solvent-based reference material set (SRM 2972) with certified values for 25(OH)D₂ and 25(OH)D₃ is also available (https://www-s.nist.gov/srmors/view_detail.cfm?srm=972). Further improvement in the agreement between laboratories and methods is expected as more laboratories use these SRMs.

Data in NHANES. The data in this report were obtained by use of an antibody-based method, specifically a radioimmunoassay (DiaSorin, Stillwater, MN). The manufacturer reformulated the kit in the late 1990s, resulting in data that were on average 12% lower than those generated with the original kit. To make NHANES III data (original kit) comparable to data from 2001–2006 (reformulated kit), we followed the recommendations of a panel of experts ([Yetley 2010](#)) to use a published adjustment equation for the NHANES III data (see Analytic Note at http://www.cdc.gov/nchs/nhanes/nhanes2005-2006/VID_D.htm). The Analytic Note also reported that the reformulated kit showed some assay drifts between 2001 and 2006. To generate 2003–2004 and 2005–2006 tables and figures, we used the public release data files from November 2010. Using data that were already adjusted for these assay drifts was the most appropriate way to make comparisons across survey cycles.

Since 1988, NHANES has monitored the vitamin D status of the U.S. population. By design, this survey collects information and biological samples in the summer from people living at higher latitudes and in the winter from people living at lower latitudes. Because the different racial and ethnic groups are not evenly distributed across all geographic regions in the United States, the season-latitude structure of the survey can affect comparisons by race or ethnicity. In two seasonal subpopulations from NHANES III (1988–1994), Looker *et al.* ([2002](#)) showed that in the winter and lower latitude subpopulation, 1–5% and 25–57% had 25(OH)D concentrations less than 25 nmol/L (10 ng/mL) and less than 62.5 nmol/L (25 ng/mL), respectively. In the summer and higher latitude subpopulation, 1–3% and 21–49% had 25(OH)D concentrations below these cutoffs. Mean 25(OH)D concentrations were highest in non-Hispanic whites, intermediate in Mexican Americans, and lowest in non-Hispanic blacks. A more recent analysis of NHANES III and NHANES 2000–2004 ([Looker 2008](#)) demonstrated that overall, mean serum 25(OH)D were 5–9 nmol/L lower in 2000–2004 than in 1988–1994 in most males, but not in most females. Factors related to changes in vitamin D status were increased body mass index, decreased milk intake, and increased usage of sun protection in the more recent surveys.

For more information about vitamin D, see the Institute of Medicine's Dietary Reference Intake reports ([Institute of Medicine 2011](#)), fact sheets from the National Institutes of Health, Office of Dietary Supplements

(http://ods.od.nih.gov/Health_Information/Information_About_Individual_Dietary_Supplements.aspx).

Highlights

Serum 25-hydroxyvitamin D [25(OH)D] concentrations in the U.S. population showed the following demographic patterns and characteristics:

- Concentrations generally decreased with increasing age.
- No consistent pattern was observed with regard to gender.
- Among the three race/ethnic groups, non-Hispanic blacks had the lowest 25(OH)D concentrations and non-Hispanic whites had the highest concentrations.
- The likelihood of being vitamin D deficient was significantly influenced by race/ethnicity.

During the past several years, the vitamin D status of the U.S. population was under intensive investigation to determine whether a downward trend was apparent. In the analysis below, we used data that were adjusted for radioimmunoassay reformulation and assay drifts according to recommendations made by a panel of experts (Yetley 2010). The age-adjusted mean 25(OH)D concentrations in the U.S. population decreased by approximately 10% between NHANES III and the periods 2001–2002 and 2003–2006 (Figure H.2.b). Decreases were seen in all groups shown (total or stratified by gender or race/ethnicity). Similarly, a recent report found that the age- and season-adjusted prevalence at risk of deficiency (serum 25(OH)D concentrations less than 30 nmol/L) increased between 1988–1994 and 2001–2002 from 4% to 7% for males aged 12 years and older and from 7% to 11% for females aged 12 years and older (Looker 2011).

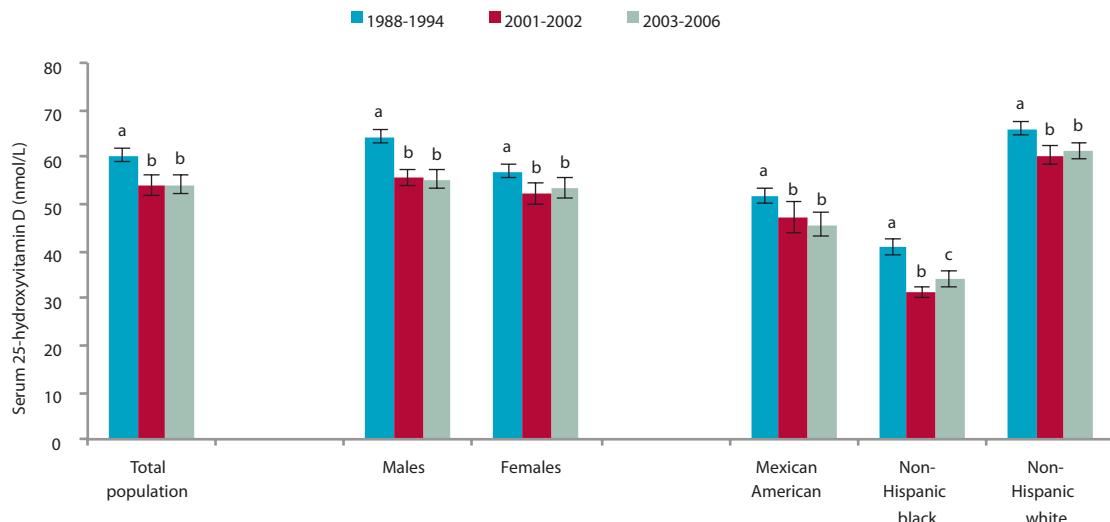

Figure H.2.b. Age-adjusted geometric mean concentrations of serum 25-hydroxyvitamin D in the U.S. population aged 12 years and older by gender or race/ethnicity, National Health and Nutrition Examination Survey, 1988–2006.

Error bars represent 95% confidence intervals. Within a demographic group, bars not sharing a common letter differ ($p < 0.05$). Age adjustment was done using direct standardization.

It is interesting to note that non-Hispanic blacks one year and older had the highest prevalence of vitamin D deficiency (serum 25(OH)D concentrations less than 30 nmol/L) (Figure H.2.c), despite clinical data showing superior bone health with greater density and fewer fractures than other race/ethnic groups; further research is needed to explain this unusual finding (Aloia 2008). Higher peak bone mass, higher obesity rates, greater muscle mass and lower bone turnover are some of the factors that have been suggested to protect African Americans against fracture

(Aloia 2008). Non-Hispanic blacks and Mexican Americans had the highest prevalence of low serum 25(OH)D concentrations categorized at risk for inadequacy (30 to less than 50 nmol/L) compared to non-Hispanic whites (Figure H.2.c).

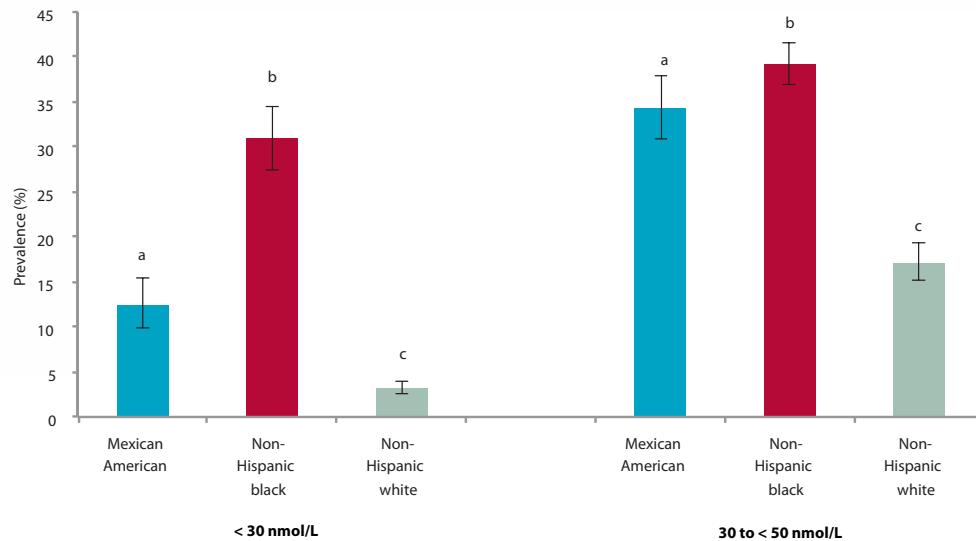

Figure H.2.c. Age-adjusted prevalence estimates of serum 25-hydroxyvitamin D concentrations less than 30 and 30 to less than 50 nmol/L in the U.S. population aged 1 year and older by race/ethnicity, National Health and Nutrition Examination Survey, 2003–2006.

Error bars represent 95% confidence intervals. Within each vitamin D status category, bars not sharing a common letter differ ($p < 0.05$). Age adjustment was done using direct standardization.

The Institute of Medicine (2011) report concluded that serum 25(OH)D levels of 40 nmol/L are at a level consistent with a desirable median intake of vitamin D. Non-Hispanic blacks had significantly higher prevalence of serum concentrations less than 40 nmol/L (Figure H.2.d) which corresponds to the targeted level for the median dietary requirement. The median meets the requirement of approximately half the population thus individuals with concentrations less than 40 nmol/L are at increased risk of adverse health outcomes.

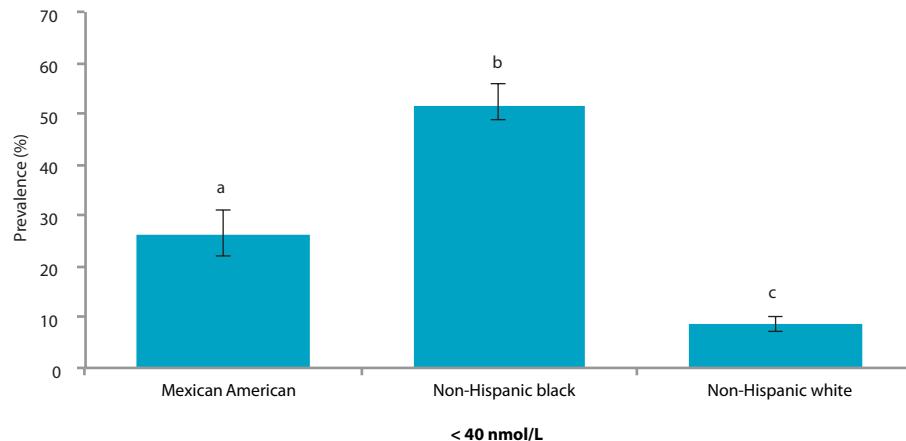

Figure H.2.d. Age-adjusted prevalence estimates of serum 25-hydroxyvitamin D concentrations less than 40 nmol/L in the U.S. population aged 1 years and older by race/ethnicity, National Health and Nutrition Examination Survey, 2003–2006.

Error bars represent 95% confidence intervals. Bars not sharing a common letter differ ($p < 0.05$). Age adjustment was done using direct standardization.

Detailed Observations

The selected observations mentioned below are derived from the tables and figures presented next. Statements about categorical differences between demographic groups noted below are based on non-overlapping confidence limits from univariate analysis without adjusting for demographic variables (e.g., age, gender, race/ethnicity) or other blood concentration determinants (e.g., dietary intake, supplement usage, smoking, BMI). A multivariate analysis may alter the size and statistical significance of these categorical differences. Furthermore, additional significant differences of smaller magnitude may be present despite their lack of mention here (e.g., if confidence limits slightly overlap or if differences are not statistically significant before covariate adjustment has occurred). For a selection of citations of descriptive NHANES papers related to these biochemical indicators of diet and nutrition, see [Appendix G](#).

Geometric mean concentrations (NHANES 2003–2006):

- Serum 25(OH)D concentrations decreased through adolescence and then stabilized (Table 2.13.a.1).
- Non-Hispanic blacks had the lowest concentrations of serum 25(OH)D (Table 2.13.a.1).

Changes in geometric mean concentrations across surveys:

- Geometric mean 25(OH)D concentrations remained steady across the survey cycles from 2001–2006 (Table 2.13.b).

Prevalence estimates of low or high biochemical indicator concentrations:

- Between 2003 and 2006, 8% of the population aged 1 year and older were at risk for vitamin D deficiency, as defined by a serum concentration < 30 nmol/L, whereas 24% had serum concentrations between 30 and less than 50 nmol/L, levels that placed them at risk for inadequacy (Tables 2.13.c.1 and 2.13.c.2). Approximately 17% of the population had concentrations < 40 nmol/L which is considered the level associated with desirable intake (Tables 2.13.c.3). Less than 1% had serum concentrations > 125 nmol/L, a level that may be reason for concern about excess (Tables 2.13.c.4).
- Less than 2% of children (1–11 years) were at risk for vitamin D deficiency (Table 2.13.c.1).
- More females (10%) than males (6%) were at risk for vitamin D deficiency (Table 2.13.c.1).
- More non-Hispanic blacks (31%) were at risk for vitamin D deficiency than non-Hispanic whites (4%) or Mexican Americans (11%) (Table 2.13.c.1).
- The prevalence of risk for vitamin D deficiency remained steady across the 2001–2006 survey cycles (Table 2.13.d.1).

Table 2.13.a.1. Serum 25-hydroxyvitamin D: Concentrations

Geometric mean and selected percentiles of serum concentrations (in nmol/L) for the total U.S. population aged 1 year and older, National Health and Nutrition Examination Survey, 2003–2006.

	Geometric mean (95% conf. interval)	Selected percentiles (95% conf. interval)					Sample size
		2.5th	5th	50th	95th	97.5th	
Total, 1 year and older	55.6 (53.6 – 57.6)	18.5 (17.4 – 19.7)	23.2 (21.4 – 25.0)	58.0 (56.3 – 59.9)	96.6 (93.9 – 101)	108 (105 – 112)	16,604
Age group							
1–5 years	68.6 (66.7 – 70.5)	36.9 (32.9 – 38.8)	41.6 (39.5 – 43.4)	68.8 (66.9 – 70.6)	99.6 (95.7 – 107)	107 (102 – 121)	1,799

Fatty Acids

Background Information

Nomenclature. Fatty acids are organic acids characterized by long unbranched aliphatic tails (4–28 carbons) attached to a carboxyl group. Fatty acids usually possess an even number of carbon atoms; and the carbon chain may contain several unsaturated or exclusively saturated bonds. Thus, fatty acids differ in chain length, degree of saturation, location of the double bond(s) along the chain, and whether the orientation of hydrogen atoms adjacent to the double bond is *cis* or *trans*. Fatty acids with no double bonds are referred to as saturated fatty acids (SFA) while those with one double bond are monounsaturated fatty acids (MUFA). Fatty acids with two or more double bonds are termed polyunsaturated fatty acids (PUFA). PUFA are most often categorized into two groups distinguished by a difference in location of the first double bond from the methyl end of the acyl chain, namely, n-6 and n-3. Linoleic acid (18:2n-6) and alpha-linolenic acid (18:3n-3) are representatives of these two groups. Each contains 18 carbon atoms but differs in the number of double bonds (18:2n-6 vs 18:3n-3) and the location of the first double bond (18:2n-6 vs 18:3n-3). In this report, unless marked, all unsaturated fatty acids are assumed to be in the *cis* configuration.

Sources and Physiological Functions. Good sources of PUFA include soybean, corn and cottonseed oils (U.S. Department of Agriculture and U.S. Department of Health and Human Services 2010). Oils that are rich in MUFA include olive, canola and safflower oils (U.S. Department of Agriculture and U.S. Department of Health and Human Services 2010). Recent NHANES data provide information on the major food sources of various fatty acids consumed in the United States (U.S. National Institutes of Health 2010a and 2010b). Chicken dishes, desserts, salad dressings, chips, nuts, seeds and pizza are the main sources of n-6 PUFA. The main sources of n-3 PUFA (C18:3n-3) in the American diet are salad dressings, chicken dishes, desserts, pizza, bread, mayonnaise and pasta dishes; whereas, the main sources of long-chain n-3 PUFA (C20:5n-3 and C22:6n-3) are fish and fish mixed dishes. The chief dietary sources of MUFA (C18:1) are desserts, meats, nuts, seeds, pizza, French fries and Mexican foods. The main sources of SFA in the American diet are full-fat cheese, pizza and desserts; other sources include chicken dishes, cured meats, ribs and burgers.

Triacylglycerols (triglycerides), the basic building blocks of fats and oils, are made up of three fatty acids esterified to a glycerol molecule (Lichtenstein 2005). They are usually composed of 2–3 different kinds of fatty acids per molecule. During digestion, dietary triglycerides from animal and vegetable fats are hydrolyzed in the small intestine to release free fatty acids. These acids enter the intestinal cells and are used to resynthesize triglycerides, which become incorporated into large lipoprotein particles called chylomicrons; these in turn are released into the lymph prior to entering the plasma. Fatty acids with 10 or fewer carbon atoms can be absorbed from the gut directly into the bloodstream where they are bound to albumin in the plasma. At distal sites, triglycerides are again hydrolyzed by lipases before fatty acids can enter cells for further metabolism. Once inside peripheral cells, free fatty acids provide an immediate source of energy (fatty acids are the body's major fuel source) or act as substrate for the biosynthesis of signaling molecules such as eicosanoids. Free fatty acids are also incorporated into other lipid classes, such as phospholipids, sphingolipids, and cholesteryl esters, or they may be resynthesized into triglycerides and stored for later use. Phospholipids, which are critical structural components of cellular membranes, tend to incorporate unsaturated fatty acids and so serve as a reservoir for MUFA and PUFA.

Humans are incapable of *de novo* synthesis of n-6 and n-3 PUFA because they lack the ability to insert a double bond any closer than 9 carbons from the methyl end. Thus, linoleic (18:2n-6) and alpha-linolenic (18:3n-3) acid are called “essential” PUFA in that they are required for good health but must be derived from food sources rather than through endogenous biosynthesis or metabolism. Both of these fatty acids are metabolized to longer-chain, more highly unsaturated forms. Note that SFA and MUFA in plasma are not expected to closely reflect dietary intake because these two classes of fatty acids can be endogenously synthesized from carbohydrates. The strongest correlations with dietary intake are provided by plasma concentrations of n-3 PUFA and *trans*-fatty acids ([Sun 2007](#)).

Health Effects. The most common MUFA is oleic acid (C18:1n-9); although humans can synthesize this fatty acid, it is obtained largely through the diet. Evidence suggests that replacing dietary carbohydrates with MUFA decreases LDL-cholesterol concentration, but there is little evidence that MUFA are associated with coronary heart disease ([Astrup 2011](#)). Currently, intense debate surrounds the question whether reduction in dietary SFA reduces risk of cardiovascular disease ([Zelman 2011](#)). At present, the Dietary Guidelines for Americans recommend reduced intake of SFA ([U.S. Department of Agriculture and U.S. Department of Health and Human Services 2010](#)). Restricting fat intake and replacing SFA with other nutrients has revealed added complexity in the diet-heart issue. According to evidence from human studies, replacing SFA with PUFA lowers coronary heart disease risk, whereas replacing SFA with carbohydrate either has no benefit ([Micha 2010](#)) or may be harmful or beneficial depending upon the quality of the carbohydrate ([Jakobsen 2009; Jakobsen 2010](#)). Carbohydrates either rapidly or slowly increase blood glucose; highly refined carbohydrates are amongst the former, and higher intake of these is associated with greater risk for development of diabetes. Replacing SFA with highly refined carbohydrates and added sugars may be increasing heart disease risk through promotion of obesity and diabetes ([Hu 2010](#)).

The heart healthy effects of PUFA are most often assessed based on their effects on the concentrations of total cholesterol, HDL- and LDL-cholesterol, cholesterol ratios and/or triglycerides. Intake of n-6 PUFA helps to lower total cholesterol and LDL-cholesterol, however, high intake of n-6 fatty acids may suppress HDL-cholesterol levels. In contrast, n-3 fatty acid consumption has been shown to maintain and even increase HDL status ([International Life Sciences Institute 2001](#)). In the United States, the FDA permits qualified health claims to be made about a diet-disease relationship for cardiovascular disease; currently, 6 of the 7 permitted claims for cardiovascular disease are related to the MUFA or PUFA content of nuts, oils and spreads, or fish oil supplements.

Deficiency in the essential fatty acids is determined by use of a plasma triene-to-tetraene ratio (eicosatrienoic [C20:3n-9]:arachidonic [C20:4n-6] acid); a ratio greater than 0.2 indicates deficiency ([Institute of Medicine 2005](#)). (Note: eicosatrienoic was not part of the plasma fatty acid profile measured for NHANES 2003-2004.) PUFA deficiency may manifest with neuropathy and skin problems, such as rough or scaly skin and dermatitis ([International Life Sciences Institute 2001](#)).

Intake Recommendations. Because the body makes more than enough SFA to meet metabolic needs, people have no requirement for these fatty acids. Evidence suggests that SFA are positively associated with total cholesterol and LDL-cholesterol concentrations and thus with cardiovascular disease risk. Lowering dietary intake of SFA to no more than 10% of caloric intake and replacing them with MUFA and PUFA is recommended to reduce the risk of cardiovascular disease; moreover, lowering the percentage of calories derived from SFA to 7% of calories, can further reduce risk of cardiovascular disease ([U.S. Department of Agriculture and U.S. Department of Health and Human Services 2010; Cleeman 2001](#)). The National Cholesterol Education Program Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (ATP III) recommends

that MUFA not exceed 20% of calories (Cleeman 2001). Guidance about adequate intake (AI) is available for the essential fatty acids. The AI of linoleic acid is 17 g/d for men and 12 g/d for women. For alpha-linolenic acid, the AI is 1.6 g/d for men and 1.1 g/d for women. Moderate evidence shows that consumption of about 8 oz of seafood per week, which provides an average of 250 mg per day of eicosapentaenoic acid (C20:5n-3) and docosahexaenoic acid (C22:6n-3), reduces cardiac deaths among persons with and without cardiovascular disease (U.S. Department of Agriculture and U.S. Department of Health and Human Services 2010). This amount of seafood is also associated with improved infant health outcomes such as visual and cognitive development, when consumed by pregnant or lactating women (U.S. Department of Agriculture and U.S. Department of Health and Human Services 2010). Currently, there is not enough evidence to establish upper tolerable limits for n-3 or n-6 PUFA (Institute of Medicine 2005).

According to the American Heart Association, patients with coronary heart disease should be encouraged to increase their consumption of eicosapentaenoic acid (C20:5n-3) and docosahexaenoic acid (C22:6n-3) to about 1 gram per day preferably from oily fish. The American Heart Association Dietary Guidelines recommend at least two servings of fish per week (particularly fatty fish) for patients without documented coronary heart disease. In addition, inclusion of vegetable oils (e.g., soybean, canola, walnut, flaxseed) and food sources (e.g., walnuts, flaxseeds) high in alpha-linolenic acid (C18:3n-3) is recommended in a healthy diet for the general population (Kris-Etherton 2002). The American Heart Association recommends 5-10% of energy from n-6 fatty acids (Harris 2009) while Adult Treatment Panel III recommends up to 10% of total calories may be consumed from polyunsaturated fats (Cleeman 2001).

Biochemical Indicators and Methods. The long term fatty acid content of the diet is best represented by the adipose tissue triglyceride content owing to the two-year half-life of adipose tissue fatty acids. Erythrocytes, due to their 120 day half-life, reflect intermediate term (weeks-to-months) dietary intake, although this idea has been challenged by data demonstrating large changes in the fatty acid composition of erythrocytes within days of altering dietary fat intake (Hodson 2008). Serum or plasma concentrations represent more recent intake (days-to-weeks). Few studies have compared the fatty acid composition of plasma with red blood cells to assess which substrate best reflects dietary intake. In one study, fatty acid correlations with food frequency questionnaire data were only slightly stronger for erythrocytes than for plasma (Sun 2007). The triglyceride fraction of plasma appears to demonstrate the greatest day-to-day variation of any circulating lipid fraction. Thus, whenever serum or plasma is collected for fatty acid analysis, fasting is preferred to minimize the within- and between-person variability at the time of specimen collection.

Capillary gas chromatography (GC) is the technique most frequently used to separate fatty acids for quantitative analysis. Detection methods include flame ionization or electron capture negative chemical ionization mass spectrometry. Internal standards are used to correct for losses during sample preparation and improve the accuracy and precision of measurements.

Data in NHANES. The data in this report were generated for fasted (\geq 8 hours) adults (\geq 20 years) by use of gas chromatography-mass spectrometry (GC-MS) based on a modification of the method of Lagerstedt *et al.* (2001). Plasma fatty acid concentrations are reported in $\mu\text{mol/L}$ units.

Generally, fatty acid data are expressed as percentage by weight of total fatty acids (wt%) although percentage by mole (mol%) would be more meaningful. The possible advantages of using absolute concentrations of individual fatty acids have not been well investigated (Hodson 2008). No data exist on plasma concentrations of fatty acids in NHANES prior to 2003. This report shows first-time NHANES data for 24 plasma fatty acids including 6 SFA, 7 MUFA, and 11 PUFA; these data were acquired using surplus plasma from NHANES 2003–2004. The serum specimens were stored at -70°C until fatty acids were measured during the period 2010–2011. Based on limited information in the literature about absolute concentrations, these 24 fatty acids are estimated to comprise at least 90% of the total fatty acids circulating in the plasma in all lipid classes (fatty acyls, glycerolipids, glycerophospholipids, sphingolipids and sterols). All unsaturated fatty acids are assumed to be in the *cis* configuration; *trans*-fatty acids were not measured.

For more information about polyunsaturated fatty acids, see the Institute of Medicine's Dietary Reference Intake reports (Institute of Medicine 2005) and fact sheets from the National Institutes of Health, Office of Dietary Supplements (<http://ods.od.nih.gov/FactSheets/Omega3FattyAcidsandHealth.asp>).

Highlights

These first-time plasma concentrations of saturated (SFA), monounsaturated (MUFA), and polyunsaturated (PUFA) fatty acids in the U.S. population showed the following demographic patterns and characteristics:

- In general, fatty acids circulated at lower concentrations in younger adults.
- Plasma concentrations of individual fatty acids were generally similar in men and women.
- No consistent race/ethnic pattern was observed for plasma fatty acid concentrations, however heart-healthy polyunsaturated fatty acids showed race/ethnic differences.

All three classes of fatty acids contained representatives at low (< 100 μmol/L) and high concentrations (> 1,000 μmol/L) (Figure H.2.e).

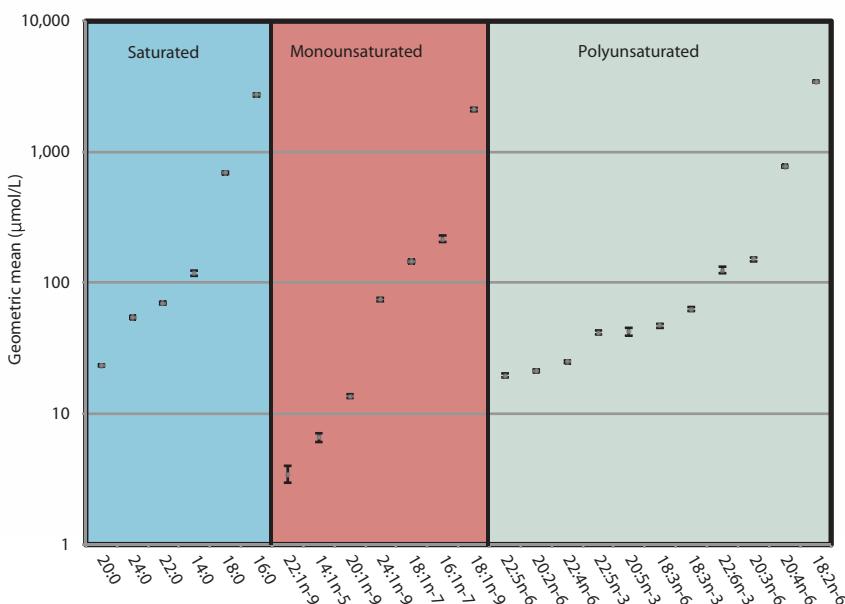

Figure H.2.e. Geometric mean plasma concentrations of individual fatty acids in the U.S. population from fasted adults aged 20 years and older by race/ethnicity, National Health and Nutrition Examination Survey, 2003-2004.

Error bars represent 95% confidence intervals. The y-axis is displayed on the logarithmic scale.

Saturated (SFA)

20:0 Arachidic acid
24:0 Lignoceric acid
22:0 Doconsanoic acid
14:0 Myristic acid
18:0 Stearic acid
16:0 Palmitic acid

Monounsaturated (MUFA)

22:1n-9 Docosenoic acid
14:1n-5 Myristoleic acid
20:1n-9 Eicosenoic acid
24:1n-9 Nervonic acid
18:1n-9 *cis*-Vaccenic acid
16:1n-9 Palmitoleic acid
18:1n-9 Oleic acid

Polyunsaturated (PUFA)

22:5n-6 Docosapentaenoic acid
20:2n-6 Eicosadienoic acid
22:4n-6 Docosatetraenoic acid
22:5n-3 Docosapentaenoic acid
20:5n-3 Eicosapentaenoic acid
18:3n-6 *gamma*-Linolenic acid
18:3n-3 *alpha*-Linolenic acid
22:6n-3 Docosahexaenoic acid
20:3n-6 *homo-gamma*-Linolenic acid
20:4n-6 Arachidonic acid
18:2n-6 Linoleic acid

Plasma concentrations of heart-healthy PUFA showed race/ethnic differences. Geometric mean concentrations of eicosapentaenoic acid (EPA), which is typically derived from seafood and supplements, were higher in fasted non-Hispanic blacks and whites compared with Mexican-American adults (Figure H.2.f).

In addition, plasma concentrations of the related long-chain polyunsaturated docosahexaenoic acid (DHA) were higher in non-Hispanic black compared with Mexican-American and non-Hispanic white adults (Figure H.2.g).

Tracking plasma fatty acid concentrations over time will show progress toward more heart-healthy diets.

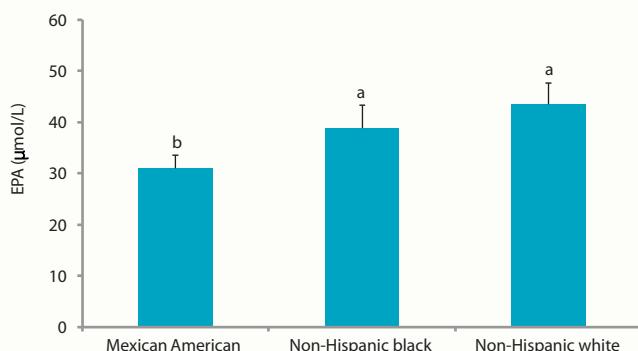

A.

Figure H.2.f. Geometric mean plasma concentrations of eicosapentaenoic acid (EPA) in the U.S. population from fasted adults aged 20 years and older by race/ethnicity, National Health and Nutrition Examination Survey, 2003-2004.

Error bars represent 95% confidence intervals. Bars not sharing a common letter differ ($p < 0.05$).

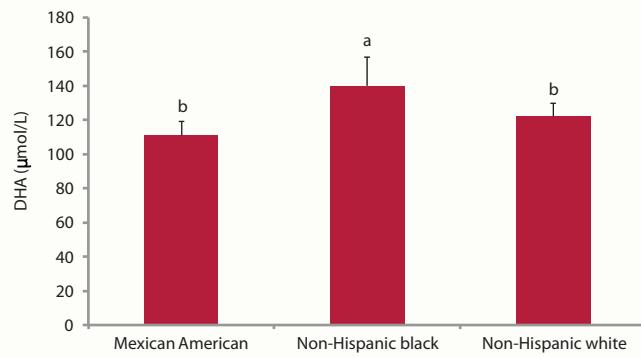

Figure H.2.g. Geometric mean plasma concentrations of docosahexaenoic acid (DHA) in the U.S. population from fasted adults aged 20 years and older by race/ethnicity, National Health and Nutrition Examination Survey, 2003-2004.

Error bars represent 95% confidence intervals. Bars not sharing a common letter differ ($p < 0.05$).

Detailed Observations

The selected observations mentioned below are taken from the tables and figures presented next. Statements about categorical differences between demographic groups noted below are based on non-overlapping confidence limits from univariate analysis without adjusting for demographic variables e.g., age, gender, race/ethnicity or other blood concentration determinants e.g., dietary intake, supplement usage, smoking, BMI). A multivariate analysis may alter the size and statistical significance of these categorical differences. Furthermore, additional significant differences of smaller magnitude may be present despite their lack of mention here e.g., if confidence limits slightly overlap or if differences are not statistically significant before covariate adjustment has occurred). For a selection of citations of descriptive NHANES papers related to these biochemical indicators of diet and nutrition, see [Appendix G](#).

Geometric mean concentrations (NHANES 2003–2004):

- The majority of fatty acids circulated in plasma at lower concentrations in younger adults 20-29 y) compared with those in the older age groups 40-59 and/or 60+ y) Tables 2.14.a.1-2.37.a.1).
- (While in general, plasma concentrations of fatty acids were similar in men and women, there were a few long chain C20-C24) exceptions in which concentrations were higher in women than in men Tables 2.14.a.1-2.37.a.1).
- (Plasma concentrations of approximately one-third of SFA and three-quarters of MUFA were found at lower concentrations in non-Hispanic blacks compared with non-Hispanic whites and/or Mexican Americans. Notably, non-Hispanic blacks had substantially lower plasma concentrations of myristic SFA) and myristoleic MUFA) acid than non-Hispanic whites or Mexican Americans Tables 2.14.a.1 and 2.20.a.1). For PUFA, the picture was mixed with each race/ethnic group having higher or lower concentrations of at least one PUFA compared with one or both race/ethnic groups.

Table 2.14.a.1. Plasma myristic acid (14:0): Concentrations

Geometric mean and selected percentiles of plasma concentrations (in $\mu\text{mol/L}$) for the fasted U.S. population aged 20 years and older, National Health and Nutrition Examination Survey, 2003–2004.

Total, 20 years and older	140 (124 – 157)	83.4 (72.4 – 90.8)	133 (118 – 152)	251 (207 – 333)	310
20–39 years	128 (107 – 153)	77.2 (66.4 – 89.0)	119 (103 – 140)	237 (177 – 367)	126
40–59 years	142 (127 – 159)	84.1† (69.9 – 95.8)	133 (119 – 157)	234† (204 – 374)	98
60 years and older	173 (155 – 193)	117† (56.2 – 135)	173 (149 – 197)	258† (216 – 368)	86
Males					
Total, 20 years and older	129 (114 – 147)	72.4 (60.4 – 82.2)	124 (110 – 145)	233 (198 – 361)	143
20–39 years	112 (89.9 – 141)	67.9† (52.5 – 76.1)	107 (84.5 – 140)	193† (143 – 367)	58
40–59 years	143 (124 – 165)	77.8† (62.1 – 89.4)	131 (113 – 171)	283† (217 – 404)	42
60 years and older	161 (138 – 189)	113† (47.5 – 127)	159 (144 – 175)	251† (195 – 368)	43
Females					
Total, 20 years and older	148 (129 – 171)	96.2 (80.8 – 104)	136 (120 – 176)	254 (203 – 442)	167
20–39 years	142 (118 – 172)	93.1† (80.7 – 98.8)	127 (106 – 186)	254† (191 – 340)	68
40–59 years	141 (121 – 165)	90.3† (47.6 – 110)	132 (119 – 163)	208† (184 – 442)	56
60 years and older	181 (162 – 201)	121† (63.8 – 136)	182 (149 – 213)	258† (222 – 351)	43

† Estimate is subject to greater uncertainty due to small cell size.

Table 2.37.a.5. Plasma docosahexaenoic acid (22:6n-3): Non-Hispanic whites

Geometric mean and selected percentiles of plasma concentrations (in $\mu\text{mol/L}$) for fasted non-Hispanic whites in the U.S. population aged 20 years and older, National Health and Nutrition Examination Survey, 2003–2004.

	Geometric mean (95% conf. interval)	Selected percentiles (95% conf. interval)			Sample size
		10th	50th	90th	
Males and Females					
Total, 20 years and older	122 (113 – 130)	69.8 (64.4 – 74.5)	117 (110 – 127)	215 (202 – 235)	992
20–39 years	111 (102 – 121)	65.2 (58.4 – 72.4)	110 (97.8 – 118)	201 (170 – 258)	300
40–59 years	118 (108 – 130)	65.9 (55.3 – 75.7)	114 (106 – 128)	206 (181 – 252)	280
60 years and older	142 (131 – 155)	84.2 (67.8 – 95.3)	136 (125 – 154)	244 (233 – 266)	412
Males					
Total, 20 years and older	113 (105 – 122)	65.3 (59.6 – 71.8)	112 (102 – 121)	198 (178 – 229)	472
20–39 years	102 (94.4 – 110)	60.8 (54.8 – 68.1)	96.1 (84.4 – 113)	180 (157 – 212)	128
40–59 years	115 (103 – 128)	64.9 (53.7 – 73.5)	113 (97.8 – 127)	194 (167 – 303)	140
60 years and older	128 (116 – 142)	77.0 (49.3 – 93.0)	121 (113 – 141)	213 (188 – 254)	204
Females					
Total, 20 years and older	130 (120 – 140)	74.4 (65.3 – 79.0)	124 (116 – 133)	229 (209 – 259)	520
20–39 years	121 (109 – 134)	72.4 (54.3 – 79.2)	114 (104 – 127)	204 (178 – 315)	172
40–59 years	122 (111 – 133)	68.0 (52.5 – 78.9)	120 (106 – 139)	207 (188 – 244)	140
60 years and older	156 (142 – 170)	89.5 (81.0 – 97.4)	150 (132 – 174)	274 (243 – 330)	208
